(Dated: August 31, 2018)

We report *ab-initio* density functional theory calculation and Raman scattering results to explore the electronic structure of Ba₅CuIr₃O₁₂ single crystals. This insulating iridate, consisting of face-sharing IrO₆ octahedra forming quasi-one-dimensional chains, cannot be described by the local $j_{eff} = 1/2$ moment picture commonly adopted for discussing electronic and magnetic properties of iridate compounds with IrO₆ octahedra. The shorter Ir-Ir distance in the face-sharing geometry, compared to corner- or edge-sharing structures, leads to strong covalency between neighboring Ir. Then this strong covalency results in the formation of molecular orbitals (MO) at each Ir trimers as the low-energy electronic degree of freedom. The theoretically predicted three-peak structure in the joint density of states, a distinct indication of deviation from the $j_{eff} = 1/2$ picture, is verified by observing the three-peak structure in the electronic excitation spectrum by Raman scattering.

The competition between covalency and electron correlations is a core concept in the study of the Mott physics [1]. A canonical example is the contrast between the Mott insulating and metallic behaviors of 3d and 4d transition-metal oxides (TMOs), respectively. In these systems, the Mott phases in 3d TMOs are attributed to the smaller covalency of 3d orbitals, *i.e.* smaller overlap integrals and the resulting stronger Coulomb repulsion [2], while the enhanced covalency and weaker Coulomb repulsion in 4d TMOs lead to metallicity [3– 5].

An interesting twist to the above simplistic picture happens in 5d TMOs, especially in iridate compounds with quasi-twodimensional layered structures [6–9] where insulating behavior with local magnetic moments were found. The key to this puzzle was found to be the presence of the strong spin-orbit coupling (SOC) in the Ir 5d orbital. Namely, SOC introduces splitting of the broad 5d bands into narrow subbands and forms spin-orbital-entangled local moments identified with the effective total angular momentum $j_{\text{eff}} = 1/2$ [10, 11]. Since then, the $j_{\text{eff}} = 1/2$ scenario has become a cornerstone in the study of correlated phases in 5d TMOs, and various theoretical suggestions of potential novel quantum phases such as high-T_c superconductivity [12, 13] or quantum spin liquid phases have been made based on this picture [14–16].

A critical necessary condition for the $j_{\text{eff}} = 1/2$ picture is the presence of (pseudo-)cubic IrO₆ octahedra, as shown in Fig. 1(a), where the Ir t_{2g} orbital ($l_{\text{eff}} = 1$) splits into the $j_{\text{eff}} = 1/2$ and 3/2 subspaces. Introducing non-cubic crystal fields can mix the two j_{eff} subspaces and break the SU(2)symmetry of the $j_{\text{eff}} = 1/2$ pseudospin. In various iridate compounds, however, such non-cubic distortions of IrO₆ octahedra were found to be not strong enough to qualitatively change the j_{eff} picture [17–20], except in a small number of examples where the non-cubic distortions are exceptionally huge [21]. Hence the belief for the validity of the j_{eff} scenario in gen-

FIG. 1. Three representative local geometries consisting of IrO_6 octahedra and their schematic energy-level diagrams. (a) depicts corner- and edge-sharing geometries where the size of spin-orbit coupling (SOC) λ_{SO} is larger than the covalency between neighboring Ir 5*d*-orbitals. (b) shows a face-sharing local geometry, where the Ir-O bond length is shorter compared to the other two cases so that the strength of *d*-*d*-covalency t_{dd} can overcome SOC. Schematic energy level diagram for each case, the conventional atomic j_{eff} -picture and a trimer molecular-orbital (MO) picture for (a) and (b) respectively, are represented.

eral iridates has become strengthened, and it has been adopted even in situations where the applicability of the scenario is not rigorously justified [22].

In this Rapid Communications, we study a material in which the local j_{eff} moment picture breaks down, and the quenching of the SOC splitting occurs not because of the non-cubic crystal fields, but because of the covalency between neighboring Ir *d* orbitals. The main message of this work is illustrated in Fig. 1, where the three representative local geometries consisting of IrO₆ octahedra — corner-, edge-, and face-sharing structures — are depicted. In terms of covalency, a critical difference between the three structures is the bond length between the nearest-neighboring Ir sites, which determines the strength of the Ir *d*-*d* direct overlap integral t_{dd} [23].

FIG. 2. $Ba_5CuIr_3O_{12}$ crystal structure employed for the *ab-initio* calculations. Copper atoms are at the center of the prism face.

While t_{dd} tends to be smaller than the size of SOC (λ_{SO}) for the corner- and edge-sharing geometries (Fig. 1(a))[24], it can be stronger than λ_{SO} for the face-sharing structures because of the shorter Ir-Ir distance. In such cases, the neighboring Ir sites should form *molecular orbitals* (MO) as depicted in Fig. 1(b). Therefore the $j_{eff} = 1/2$ local moment picture in the face-sharing geometry breaks down and the effects of SOC and Coulomb interactions should be considered based on the MO description.

By combining Raman spectroscopy measurements and abinitio theoretical analyses, we study a mixed 3d-5d insulator $Ba_5CuIr_3O_{12}$ for which the $j_{eff} = 1/2$ approach breaks down [25, 26]. In this compound, sequences of trigonal prismatic and octahedral transition metal sites run in chains parallel to the crystallographic z-axis, with Ba atoms located between the chains [Fig. 2]. Ab-initio calculations and a tightbinding (TB) analysis yield a MO description of the electronic structure originating from the face-sharing geometry as depicted in Fig. 1(b), and predict a three-peak structure in the joint density of states (JDOS). Raman scattering, a technique successfully used to study electronic excitations in iridate compounds [27], verifies this prediction. We observe one strong and sharp excitation at 0.58 eV, and two weak features at 0.66 and 0.74 eV. It should be noted that such a threepeak structure is not observed in systems with well-defined $j_{\text{eff}} = 1/2$ local moments [27].

We identify the structural motif for Ba₅CuIr₃O₁₂ to be the three face-sharing IrO₆ octahedra forming an Ir trimer as shown in Fig. 1(b) and Fig. 2. If the intra-Ir-trimer hybridization dominates SOC, the three Ir t_{2g} orbitals at the trimer sites split into nine MOs [Fig. 3(a)]. Among those, the atomic a_{1g} singlet at each site gives rise to the strongest σ -type overlap between neighboring Ir sites; while the other e'_{g} doublets lead to weaker π - or δ -like overlaps. Such scenario can be tested by constructing a simple TB model and comparing the results

FIG. 3. (a) Energy level diagram showing the splitting of the Ir t_{2g} states in an Ir trimer into MO states. Here $\sigma/\pi/\delta$, $\bar{\sigma}/\bar{\pi}/\bar{\delta}$, and $\sigma^*/\pi^*/\delta^*$ denote bonding, nonbonding, and antibonding states, respectively. Electrons in fully filled states are represented by circles, while magnetically active electrons are represented by arrows. (b,c) Projected DOS from the simple tight-bonding model for Ir trimers (b), and from *ab-initio* calculations without SOC and magnetism (c). The color scheme for the orbital character is the same in (a-c).

with those from DFT calculations. For the TB model, as a first-order approximation, we assume a three-fold symmetry along the z direction and ignore the Cu-Ir hybridization. After this simplification, just four free parameters are left for the Ir trimer model where the parameters are tuned to fit the DFT DOS afterwards [28]. Note that, because this is a test for the molecular orbital picture, SOC and the on-site Coulomb interactions are not considered at this stage.

Fig. 3 presents the comparison between the TB model and the DFT results, where Fig. 3(a), (b), and (c) show the schematic TB energy diagram, TB DOS, and DFT DOS respectively. Both the a_{1g} - and e'_{g} -derived MO states, depicted in blue and red in Fig. 3, show bonding $(\sigma/\pi/\delta)$, nonbonding $(\bar{\sigma}/\bar{\pi}/\bar{\delta})$, and antibonding $\sigma^*/\pi^*/\delta^*$ characters [Fig. 3(a)]. Remarkably, the DOS from the simple 4-parameter-model agrees quite well with the DFT DOS; features of the DOS obtained from DFT calculations are consistent with those derived from the TB analysis, especially that the nonbonding $\bar{\sigma}/\bar{\pi}/\bar{\delta}$ -MOs are located only at the two ends of the trimer [Fig. 3(b) and (c)]. The bonding-antibonding splitting between the σ - and σ^* -MO is 2.5 eV, much larger than the strength of SOC (0.4 eV) [10]. Therefore the intra-Ir-trimer hybridization indeed dominates SOC.

Since the size of MO splitting is large, we only need to consider the effect of SOC near the Fermi level. Fig. 4 illustrates how SOC and the Coulomb interaction induce a spin

polarization within the $\sigma^*/\pi^*/\delta^*$ MOs and in turn open a gap. First the Coulomb interaction induces a 'high-spin-like' configuration by fully polarizing the spins within the π^*/δ^* and σ^* states. Then, because the π^*/δ^* MOs carry atomic orbital angular momenta $l_{eff}^z = \pm 1$, SOC functions as an orbital Zeeman field that splits the π^*/δ^* MOs [compare Fig. 4(a) and (b)]. A three-peak structure therefore appears in the unoccupied sector as shown in Fig. 4(c) where the a_{1g}/e'_{g} -projected DOS from the DFT+U [29] calculation with SOC included is plotted. The three peaks, α , β , and γ in the JDOS from the DFT+U result [Fig. 4(d)] originate from the transitions from the highest occupied MO state with $j_{eff}^z = 0$ to the unoccupied MO states with $j_{\text{eff}}^z = +1/2$, 0, and -3/2, respectively. Note that the inclusion of U tends to recover the local atomic picture by mixing MO states, as shown in Fig. 4(c), where there is a small mixture among the $j_{\text{eff}}^z = +1/2$, 0, and -3/2 MO states. This effect, however, does not qualitatively affects the above MO description.

To confirm the predicted three-peak structure in the electronic excitation spectrum, we perform Raman-scattering measurements in a quasi-back-scattering geometry from the (100) crystallographic surface of Ba₅CuIr₃O₁₂ single crystal grown by flux method [see Supplementary Materials for details of sample preparation and Raman scattering]. We use 476.2 nm line from a Kr⁺ ion laser for excitation. Incident light with ~10 mW power is focused to a $50 \times 100 \,\mu\text{m}^2$ spot.

Fig. 5 shows the Raman spectrum measured at 25 K. The sharp features at 17, 41 and 84 meV are phonon modes [see Supplementary Materials for the low-energy Raman spectrum]. The two peaks at 130 and 170 meV result from second-order phonon scattering (41+84 meV and 84+84 meV, respectively). The broad feature centered at 240 meV, weaker and broader than the second-order phonon scattering peaks, is attributed to third-order phonon scattering (84+84+84 meV).

Importantly, three high-energy electronic excitations at 0.58, 0.66 and 0.74 eV are resolved. The high-energy Raman spectrum exhibits the general trends of the JDOS from DFT+U. The high-energy gap in the Raman spectrum is about 0.55 eV, while it is 0.70 eV in the JDOS. The three peaks in the Raman spectrum are evenly spaced, with a separation of 0.08 eV; those in the JDOS are also evenly spaced but with a 0.2 eV separation. One possible reason for the smaller splitting in experimental spectrum compared to the DFT+U JDOS peak splitting can be a stronger mixing between the $l_{\text{eff}}^z = \pm 1$ and 0 antibonding MO states near the Fermi level in the real system. This mixing reduces the expectation value of SOC energy and in turn decreases the separation. Another thing to mention is, while in the JDOS all the three peaks have similar spectral weight, in the Raman spectrum the 0.58 eV peak is much stronger than the other two. This could be attributed to the matrix element effect.

The three-peak structure in the DFT+U JDOS and in the Raman measurement is a distinct feature indicating deviation from the $j_{\text{eff}} = 1/2$ picture. Simple $j_{\text{eff}} = 1/2$ picture predicts up to two high-energy transition peaks, because non-cubic crystal fields just induce splitting of the fully occu-

FIG. 4. (a) Schematic diagram showing the MO levels with SOC and U not included. The l_{eff}^z eigenvalues are given. (b) Schematic diagram showing the MO levels with SOC and U included. The J_{eff}^z eigenvalues are given. (c) Projected DOS from DFT+SOC+U calculations for the a_{1g} and e'_g states at Ir sites. pied $j_{\text{eff}} = 3/2$ quartet [10, 18]. On the contrary, our threepeak structure in Ba₅CuIr₃O₁₂ comes from the strong Ir-Ir hybridization in the face-sharing IrO₆ octahedral geometry and the resulting formation of MOs. We note that in other compounds with similar face-sharing geometries with alternating 3*d* and 5*d* transition metal ions such as Sr₃NiIrO₆ [30] or Sr₃CuIrO₆ [20], two-peak structures are observed in their j_{eff} -excitation spectra [18]. This implies that, although the size of non-cubic distortions is large in these compounds, still the local $j_{\text{eff}} = 1/2$ moment picture remains effective because of the reduced covalency between the 3*d* and 5*d* orbitals as suggested in a recent *ab-initio* study for Sr₃NiIrO₆ [31]. We also comment that there is another theoretical study on BaIrO₃ [22], consisting of the same face-sharing Ir₃O₁₂ octahedral trimers like Ba₅CuIr₃O₁₂. A similar three-peak struc-

FIG. 5. Raman spectrum $\chi''(\omega)$ at 25 K. Sharp features below 0.1 eV are phonon modes; the two peaks at 0.13 and 0.17 eV result from second-order phonon scattering while the broad feature at 0.24 meV originates from third-order phonon scattering. The three high-energy electronic excitations at 0.58, 0.66 and 0.74 eV are labeled by α , β , and γ respectively, corresponding to the labeling in Fig. 4(d).

ture in the upper Hubbard band (UHB) was reported therein, but it was speculated that the UHB states still retain the $j_{\rm eff} = 1/2$ character, which seems to require a more rigorous justification.

As for possible magnetism in this compound; from the projected DOS plotted in Fig. 4(b) and (c), we identify three magnetically active states; a σ^* state with mostly $a_{1\mathrm{g}}~(l_{\mathrm{eff}}^z\,{=}\,0)$ character mainly located at Ir 2 site, and two π^*/δ^* states with the $e'_{\rm g}$ character $(l^z_{\rm eff} = \pm 1)$ at Ir 1 and 3 sites. The strong SOC within the Ir d-orbital then behaves as a single-ion anisotropy to the electron spins filling the $l_{eff}^z = \pm 1$ MO states, locking the spins parallel to the z-direction. Spin in the $l_{\text{eff}}^z = 0$ MO state, on the other hand, has little single-ion anisotropy due to the vanishing orbital angular momentum. The spin moments at Cu sites are also isotropic, so this compound should have three different kinds of spin moments: isotropic Cu spins, isotropic Ir spins at Ir 2 sites, and anisotropic Ir spins at Ir 1 and 3 sites locked along the z-direction. Because all the Ir spins are occupying the MO states, rather than behaving as the $j_{\text{eff}} = 1/2$ local moments, they may show distinct low-energy magnetic properties compared to previously known magnetic iridate compounds. For future studies, interesting questions about the outcome of MO formation can be posed, for example on the form of exchange interactions and the spectrum of low-energy magnetic excitations.

Our study on the face-sharing iridate Ba₅CuIr₃O₁₂ demonstrates the breakdown of the SOC-based $j_{\text{eff}} = 1/2$ physics, and reveals the MO nature of the electronic structure originating from the strong intermetallic *d*-*d* direct overlap. A similar scenario, leading to the formation of benzene-ring-shaped quasimolecular orbitals (QMO) driven by π -like *d*-*p* overlap, was suggested for Na₂IrO₃ [32]. In Na₂IrO₃, the *d*-*p* overlap preserves the three-fold symmetry of the Ir t_{2g} orbitals, hence the inclusion of SOC and *U* induces a crossover from the delocalized QMO to the local $j_{\text{eff}} = 1/2$ moment picture [33]. In Ba₅CuIr₃O₁₂, on the contrary, the direct overlap t_{σ} is not only huge but also explicitly breaks the degeneracy of the Ir t_{2g} orbitals, resulting in a completely different MO description. Overall, this work suggest a peculiar relation between the crystal structure and the nature of electronic degree of freedom in 5*d* iridate and other transition metal compounds, which can be useful in search of novel correlated materials.

M.Y. thanks H.-H. Kung for helpful comments on the early version of the manuscript. Crystal growth (C.-J. W.) was supported by the National Research Foundation of Korea, Ministry of Science and ICT (No. 2016K1A4A4A01922028). The DFT study (H.-S.K., D.V., K.H.) and and the crystal characterization (J.-W.K., S.-W.C.) were supported by NSF DM-REF DMR-1629059. The spectroscopic work (M.Y., G.B.) was supported by NSF Grant No. DMR-1709161.

M.Y. performed the spectroscopic study and H.-S.K. did the *ab-initio* calculations. These two authors contributed equally to this work.

Computational details

Ab-initio simulations

For our *ab-initio* simulations, we first assume a crystal structure with no disorder in Cu positions, that Cu are located at one of the three equivalent prismatic facial positions as shown in Fig. 2 in the main text. Further, no Cu-Ir intermixing is considered. The unit cell contains 6 formula units, i.e. three Ir-Cu chains. It should be commented that, for a better reproduction of the experimentally measured spectra one may need to take an average over *ab-initio* calculations from all possible orderings of Cu to restore the three-fold rotation symmetry along the chain direction. For a qualitative understanding of the high-energy spectra, however, the current result from the choice of Cu ordering shown in Fig. 2 in the main text seems to be enough.

The Vienna *ab-initio* Simulation Package (VASP), which uses the projector-augmented wave (PAW) basis set [36, 37], was employed for structural optimizations and electronic structure calculations. 400 eV and a Γ -centered 3x3x3 *k*point grid were used for the plane wave energy cutoff and the *k*-point sampling, respectively. A revised Perdew-Burke-Ernzerhof generalized gradient approximation for crystalline solids (PBEsol) was chosen for the exchange-correlation functional [38], and 10^{-2} eV/Å of force criterion was used for the structural optimization. A simplified rotationally-invariant form of DFT+*U* method [29] was employed to treat the on-site Coulomb interaction both at Cu and Ir sites with the spin-orbit coupling (SOC) included.

Tight-binding model

Assuming the three-fold rotational symmetry along the chain direction (*i.e.* ignoring the IrO_6 octahedral distortions other than the trigonal one), and also assuming the Ir-Ir hybridizations are dominating those from Ir-Cu (this choice is justified by DFT calculations which show small hybridization between Ir and Cu *d*-orbitals), the three-site tight-binding model can be written as follows,

$$H_{\rm TB} = \begin{pmatrix} 0 & \Delta_{\rm tri} & \Delta_{\rm tri} & t_1 & t_2 & t_2 & 0 & 0 & 0 \\ \Delta_{\rm tri} & 0 & \Delta_{\rm tri} & t_2 & t_1 & t_2 & 0 & 0 & 0 \\ \Delta_{\rm tri} & \Delta_{\rm tri} & 0 & t_2 & t_2 & t_1 & 0 & 0 & 0 \\ \hline t_1 & t_2 & t_2 & \epsilon_{\rm on} & \Delta_{\rm tri} & \Delta_{\rm tri} & t_1 & t_2 & t_2 \\ t_2 & t_1 & t_2 & \Delta_{\rm tri} & \epsilon_{\rm on} & \Delta_{\rm tri} & t_2 & t_1 & t_2 \\ \hline t_2 & t_2 & t_1 & \Delta_{\rm tri} & \Delta_{\rm tri} & \epsilon_{\rm on} & t_2 & t_2 & t_1 \\ \hline 0 & 0 & 0 & t_1 & t_2 & t_2 & 0 & \Delta_{\rm tri} & \Delta_{\rm tri} \\ 0 & 0 & 0 & t_2 & t_1 & t_2 & \Delta_{\rm tri} & 0 & \Delta_{\rm tri} \\ \hline 0 & 0 & 0 & t_2 & t_2 & t_1 & \Delta_{\rm tri} & \Delta_{\rm tri} & 0 & \Delta_{\rm tri} \end{pmatrix}$$

where t_1 and t_2 are nearest-neighbor hopping integrals between the same and different kinds of Ir t_{2g} orbitals respectively, Δ_{tri} is the on-site trigonal crystal field within the t_{2g} complexes, and ϵ_{on} is the on-site energy difference between the central and lateral Ir. The projected density of states in Fig. 3(b) in the main text was calculated by choosing $t_1 = -0.43 \text{ eV}$, $t_2 = -0.20 \text{ eV}$, $\Delta_{\text{tri}} = -0.12 \text{ eV}$, and $\epsilon_{\text{on}} = -0.3 \text{ eV}$, which yielded qualitative agreement with the *ab-initio* results as discussed in the main text. Note that, if we take the unitary transform to the trigonal basis set (a_{1g} and e'_{g} states), the σ -like overlap between the a_{1g} states becomes $t_1 + 2t_2 = -0.83$ eV, twice larger than the SOC of Ir ($\lambda_{\text{SO}} \simeq 0.4 \text{ eV}$), supporting the molecular-orbital scenario.

Experimental details

Material preparation

Single crystals of Ba₅CuIr₃O₁₂ are grown by flux method; details of growth and characterization will be published separately. This material has a trigonal structure (space group P3c1, No.158; point group C_{3v}) [25, 26]. The sample is polished with a lapping film (1 micrometer, Buehler) and is subsequently annealed at 650 °C in air to remove residual strain. Its annealed (100) crystallographic surface is then used for Raman measurements.

Raman scattering

Raman-scattering measurements are performed in a quasiback-scattering optical setup. The 476.2 nm line from a Kr⁺ ion laser is for excitation. Incident light with ~10 mW power is focused to a 50×100 μ m² spot on the (100) crystallographic surface. Environmental temperature of 20 K is achieved in a helium-gas-cooled cryostat, and the laser heating is assumed to be 0.5 K/mW. We use a custom triple-grating spectrometer and a liquid-nitrogen-cooled charge-coupled device (CCD) detector for collection and analysis of the scattered light. The data are corrected for the system background and the spectral response. The measured scattering intensity $I(\omega, T)$ is related to the Raman response $\chi''(\omega, T)$ by $I(\omega, T) = [1 + n(\omega, T)]\chi''(\omega, T)$, where *n* is the Bose factor, ω is Raman shift and *T* is temperature.

Low-energy Raman spectrum

Fig. S6 shows the low-energy Raman spectrum of $Ba_5CuIr_3O_{12}$ at 25 K. The sharp features at 17, 41 and 84 meV are identified as phonon modes. The 17 meV mode primarily involves motion of Ir atoms, and the 84 meV mode is derived from vibration of O atoms. The broad feature centered at 40 meV could be a bundle of phonon modes related to the motion of Ba atoms. The two weak features at 60 and 78 meV are also likely phonon modes.
