In single sheets of graphene, vacancy-induced states have been shown to host an effective spin-1/2 hole that can be Kondo-screened at low temperatures. Here, we show how these vacancy-induced impurity states survive in twisted bilayer graphene (TBG), which thus provides a tunable system to probe the critical destruction of the Kondo effect in pseudogap hosts. Ab-initio calculations and atomic-scale modeling are used to determine the nature of the vacancy states in the vicinity of the magic angle in TBG, demonstrating that the vacancy can be treated as a quantum impurity. Utilizing this insight, we construct an Anderson impurity model with a TBG host that we solve using the numerical renormalization group combined with the kernel polynomial method. We determine the phase diagram of the model and show how there is a strict dichotomy between vacancies in the AA / BB versus AB / BA tunneling regions. In AB / BA vacancies, we find that the Kondo temperature at the magic angle develops a broad distribution with a tail to vanishing temperatures due to multifractal wavefunctions at the magic angle. We argue that the scanning tunneling microscopy response in the vicinity of the vacancy can act as a non-trivial probe of both the critical single-particle states and the underlying many-body ground state in magic-angle TBG.

Twisted van der Waals heterostructures have taken the condensed matter community by storm [1–3]. Since the first experimental evidence demonstrating the band reconstruction and emergence of a flat band in twisted bilayer graphene (TBG) at twist angle $\sim 1^\circ$ [4], a wide range of experimental evidence and technical breakthroughs [5–8] have paved the way for the discovery and reproducible observations of correlated insulating states [9] and superconductivity [10] in magic-angle TBG, demonstrating the vast potential and intriguing properties of these moiré materials. These ideas have now been extended to twisted bilayer transition metal dichalcogenides [11–15], quantum magnets [16, 17], high-temperature superconductors [18–22], and bosonic superfluids in optical lattices [23–25]. To unravel the nature of the underlying many-body states in moiré materials, it is essential to explore new ways to extract electron correlations while using current experimental capabilities.

One potentially fruitful direction is to probe the nature of impurity states, which can be accurately measured with scanning tunneling microscopy (STM), in order to gain insights into the many-body ground state that the impurity states are coupled to. For instance, the tunneling spectra of impurity-induced resonances in superconductors reveal signatures of the pairing symmetry [26]. In the case of single sheets of graphene, creating impurity states that are strongly coupled to the itinerant electrons was a challenge until it was realized that vacancy-induced bound states act like a spin-1/2 hole, originating from the vacancy's nearest-neighbor σ states which couple to the π -band due to the non-zero local curvature near the vacancy site [27–32]. This represents a clear-cut realization of the pseudogap Anderson impurity model (AIM), which features a quantum critical point at non-zero Kondo coupling [33–45]. However, experimentally observing this

quantum critical point has remained out of reach due to the lack of tunability of the vacancy states, despite the observation of Kondo screening in graphene hosts [31, 46].

In this work, we study vacancy-induced impurity states in TBG away from and at the magic angle using a combination of atomic-scale and effective lattice model Hamiltonians. Using ab-initio calculations, we show that a vacancy [47] induces an effective spin-1/2 hole and compute the hybridization functions for the vacancy and the twisted pair of π -bands, showing a clear dichotomy between AA- and AB-dominated tunneling regimes. We use these insights to construct an effective quantum impurity model [48], which is solved using a combination of the kernel polynomial method [49] and the numerical renormalization group [50] (KPM+NRG [51]). Away from the magic angle, we show that this realizes a tunable, pseudogap AIM where the twist of the bilayers can be used to tune the vacancy through its quantum phase transition. At the magic angle, we find that the impurity is always Kondo-screened at low temperatures. We study the distribution of Kondo temperatures T_K across the sample to show how T_K in the AB region is strongly suppressed relative to the AA region.

Microscopic picture.—To set the stage, we investigate how the vacancy σ (V_σ) state in TBG at the magic angle ($\theta_M = 1.05^\circ$ [56]) hybridizes with the twisted pair of π -bands using an accurate machine-learned tight-binding model [57], combined with embedded V_σ states given by density functional theory (DFT) calculations [58]. Figure 1(c) shows the structure of TBG at θ_M obtained by relaxing a non-corrugated, free-standing configuration using the interlayer potential [59, 60] with the method described in Ref. [61, 62], performed using the molecular dynamics (MD) simulation package LAMMPS [63]. Figure 1(a) shows the band structure of pristine TBG obtained given by the atomic-scale

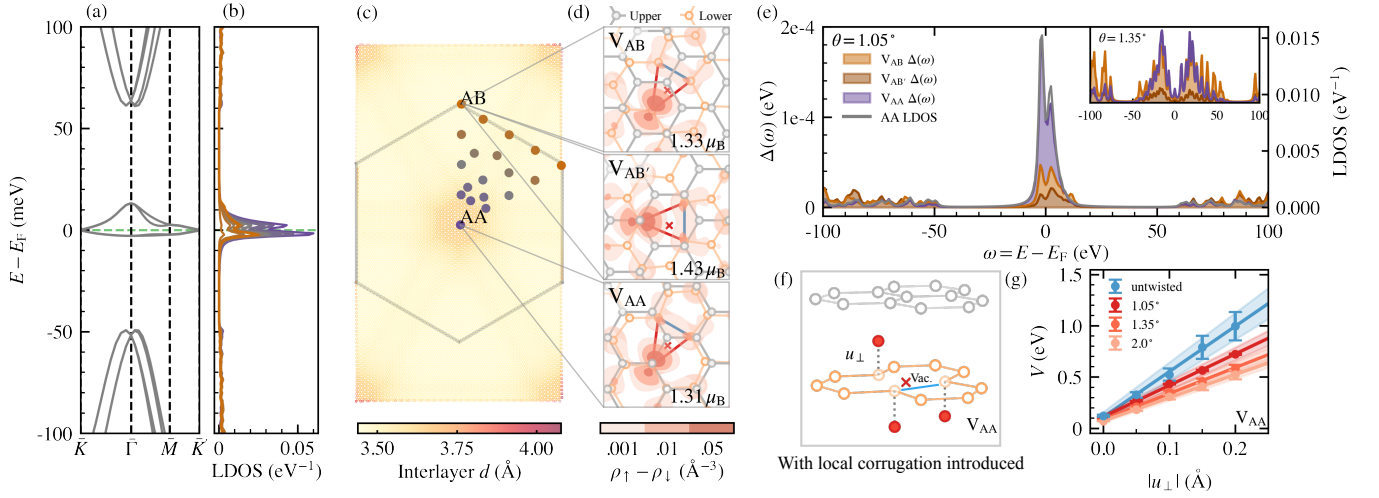

FIG. 1. Atomic-scale modeling of TBG with a vacancy. (a) Band structure of pristine TBG at θ_M without vacancy. \bar{K} and \bar{K}' indicate the two valleys of the moiré Brillouin zone. (b) Projected local density of states (LDOS) at the potential vacancy sites denoted in (c), color-coded. (c) The C atoms in the relaxed pristine TBG at θ_M , with the center of AA and AB regions annotated. The atoms are colored-coded according to the local interlayer spacing. The hexagon represents the moiré unit cell. The 19 potential vacancy sites chosen for computing LDOS in (b) are indicated by thicker dots. (d) $\rho_{\uparrow} - \rho_{\downarrow}$ for the three vacancy configurations, computed in untwisted bilayer graphene using DFT. V_{AB} and $V_{AB'}$ vacancies could be present in TBG AB regions, while V_{AA} vacancies are typical in AA regions. The grey (orange) circles denote the C atoms in the upper (lower) layers, and the red cross denotes the vacancy. The blue (red) lines highlight the shorter (longer) distances between three adjacent sites. The clouds of $\rho_{\uparrow} - \rho_{\downarrow}$ are plotted in red, showing that most of the excessive spin is contributed by the σ -lobe at the isolated adjacent site. (e) Computed hybridization function at θ_M between the V_{σ} state and the TBG bath for the three vacancy configurations. The LDOS for the AA site is also plotted in the grey curve for comparison. The insets show the hybridization at twist angle 1.35° , which features a Dirac-cone-like low-energy dispersion with larger flat-band bandwidth compared with 1.05° . (f) Side view of the AA-stacked bilayer graphene near the vacancy site, with manual vertical displacements of the three adjacent sites away from equilibrium, denoted as u_{\perp} . The bonded sites (connected by a blue line) are displaced downwards with the same value of u_{\perp} . (g) Computed hybridization strength V between the V_{σ} state and the bath versus u_{\perp} for the untwisted V_{AA} vacancy (blue) and when coupled to the TBG bath (red). The lines are linear fits of the data, showing that V is tunable by changing u_{\perp} and the twist angle.

tight-binding model, and Fig. 1(b) the local density of states (LDOS) projected onto the potential vacancy sites indicated in panel (c). One finds that the flat-band states are mostly localized at the AA regions (except at Γ) and have decreasing projections onto sites further away from the AA center. This indicates that an impurity in the AA (AB) regions hybridizes more (less) with the localized flat-band states.

To understand the microscopic mechanism of how vacancy states hybridize with the π -bands in TBG, we start by considering a monovacancy in single-layer graphene. Removing one atom leaves dangling vacancy V_{π} and V_{σ} orbitals at the three adjacent atoms, which undergo a Jahn–Teller distortion such that one isolated atom moves further away from the vacancy, and the other two atoms move closer to re-bond. This results in one V_{σ} state localized at the isolated site near the Fermi level and a V_{π} quasi-localized zero mode [28, 29]. In the experimentally relevant regime, the effect of the V_{π} zero mode can be qualitatively captured by a renormalization of the V_{σ} Coulomb interaction [31], and we will thus focus on the V_{σ} state in the following.

In single-layer graphene, the coupling between the V_{σ} state and the π -bands requires a finite local corrugation that breaks the mirror symmetry [31, 32]. By contrast, this coupling arises naturally if a second, untwisted layer is stacked onto

free-standing graphene, which breaks the mirror symmetry near the vacancy site at the lower layer. To capture this, we performed DFT calculations using a 6×6 supercell of untwisted bilayer graphene with one vacancy on the bottom layer in three different local environments [58], named after the registry of the two sheets of graphene and note that, in AB-stacked graphene, there are two types of vacancies, V_{AB} and $V_{AB'}$ (see Fig. 1(d)). Similar to single-layer graphene, the three adjacent atoms near the vacancy site relax to a final equilibrium configuration, showing almost no corrugation near the vacancy. Figure 1(d) shows the calculated excessive spin density, $\rho_{\uparrow} - \rho_{\downarrow}$ [64], which is centered at the isolated adjacent C atom, contributed mainly by the σ -lobe toward the vacancy. The details of the calculations and the electronic structure of bilayer graphene with a vacancy are summarized in [58].

Considering describing the vacancies in TBG in the dilute limit, we expect the 6×6 supercell simulation of the V_{σ} state in untwisted bilayer graphene to mimic the actual vacancy in TBG near θ_M . Using our DFT results in untwisted bilayer graphene, we compute the hybridization function between the dangling V_{σ} state and the “bath” (TBG *without* the vacancy

and its three adjacent sites),

$$\Delta_{\text{micro}}(\omega) = \pi \sum_{n,\mathbf{k}} |T_{n\mathbf{k}}|^2 \delta(\omega - E_{n\mathbf{k}}), \quad (1)$$

where the subscript “micro” indicates that it is derived from the microscopic model. Here, $T_{n\mathbf{k}} = \langle \phi_{V_\sigma} | H_{V_\sigma\text{-bath}} \mathcal{P}_{\text{bath-TBG}} | \psi_{n\mathbf{k}} \rangle$ represents the tunneling matrix element between the V_σ state $|\phi_{V_\sigma}\rangle$ and the pristine TBG eigenstate $|\psi_{n\mathbf{k}}\rangle$ with eigenvalue $E_{n\mathbf{k}}$. $H_{V_\sigma\text{-bath}}$ is the hopping between the V_σ state and the C atoms in the bath; $\mathcal{P}_{\text{bath-TBG}}$ projects the TBG eigenstate from the Hilbert space of N -site TBG to that of the $(N-1)$ -orbital π bath. The computed $\Delta_{\text{micro}}(\omega)$ is shown in Fig. 1(e) for the three vacancy local environments at θ_M compared with the LDOS, with insets showing the result at 1.35° . Compared with the other two vacancy types, V_{AA} hybridizes much stronger with the bath, especially with the flat-band states.

In the experiment, the substrate almost always induces a finite local corrugation in TBG, which is not captured by our MD simulations. Therefore, we manually introduced local corrugation near the vacancy to study how it changes the hybridization strength. Figure 1(f) shows the schematic side view of how the three vacancy-adjacent atoms are displaced by u_\perp either upwards or downwards [58] for a V_{AA} vacancy. Figure 1(g) shows that the hybridization strength V increases with u_\perp and decreases with twist angle. As $u_\perp > 0.2 \text{ \AA}$, a localized V_σ state can no longer be identified. We find that V_{AA} vacancies are most sensitive to twisting [58].

To summarize, a vacancy in bilayer graphene induces a localized spin density nearby, which hybridizes with the π bath with a strength tunable via the local environment, atomic corrugation, and the twist angle, suggesting that TBG with a monovacancy realizes a tunable, pseudogap AIM. To make the AIM tractable, we turn to constructing an effective impurity model with the parameters of the impurity derived from the microscopic model and the hybridization function described by a simpler TBG bath. The latter has all of the salient features we have just found but will allow us to describe the spectral properties of TBG down to sufficiently low energy scales to treat the Kondo effect accurately.

Quantum impurity model.—We use the AIM, with the Hamiltonian $H = H_{\text{host}} + H_{\text{hyb}} + H_{\text{imp}}$, to emulate TBG with a vacancy. The host contributions are typically written in the single-particle eigenbasis, where ϵ_k is the eigenenergy of a state created by $c_{k\sigma}^\dagger$ with a wavefunction $\phi_{k\sigma}(j) = \langle j, \sigma | \epsilon_k \rangle$ at lattice site j . Then,

$$H_{\text{host}} = \sum_{k,\sigma} \epsilon_k c_{k\sigma}^\dagger c_{k\sigma}, \quad H_{\text{hyb}} = V \sum_{\sigma} [d_\sigma^\dagger c_{R\sigma} + \text{H.c.}], \quad (2)$$

where R labels the impurity site, $c_{R\sigma} = \sum_{\mathbf{k}} \phi_{\mathbf{k}}(R) c_{\mathbf{k}\sigma}$, and $V > 0$ is the hybridization strength. The effect of the host on the impurity is fully described by the hybridization function

$$\Delta_R(\omega) = \pi V^2 \sum_{\mathbf{k}} |\phi_{\mathbf{k}}(R)|^2 \delta(\omega - \epsilon_{\mathbf{k}}) \equiv \pi V^2 \rho_R(\omega), \quad (3)$$

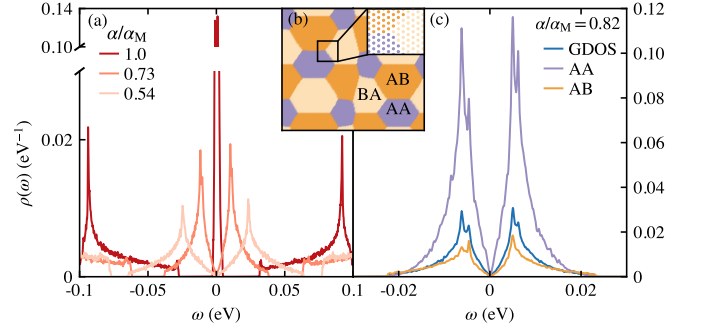

FIG. 2. Hybridization functions for the effective lattice model of TBG in Eq. (2). (a) The model GDOS at different twist parameters, where $\alpha = 0.081$ ($w = 0.11 \text{ eV}$) corresponds to the magic angle. (b) Tunneling map, where different colors indicate the locally dominating tunneling according to the effective lattice model [58]. The inset shows the microscopic lattice spacing across a patch. (c) Comparison of GDOS and LDOS in the AA and AB regions at $\alpha = 0.067$ ($w = 0.09 \text{ eV}$). The LDOS is averaged over 200 samples of random twisted boundary conditions; the GDOS is additionally averaged over the origin of rotation in TBG across 400 samples.

with ρ_R the host LDOS per spin orientation ($\phi_{\mathbf{k}} \equiv \phi_{\mathbf{k}\sigma}$). One approximation we consider to help gain physical insight into the problem ignores the spatial contribution of the wavefunction to the LDOS, so that the LDOS in the hybridization function is replaced by the global DOS (GDOS, per spin orientation, per lattice site) $\rho(\omega) = N^{-1} \sum_{\mathbf{k}} \delta(\omega - \epsilon_{\mathbf{k}})$.

As our host, we use a microscopic lattice model of TBG [65] derived from the Bistritzer–MacDonald continuum model [56, 58]. It is characterized by the twist angle θ and the interlayer tunneling w . We can modify the hybridization function by varying either of them, since only their ratio matters at small twist angles in the form $\alpha \equiv w/[2v_F k_D \sin(\theta/2)]$. Here, the Fermi velocity is $v_F = 3ta_0/(2\hbar)$ with $t = 2.8 \text{ eV}$, and the distance from the Γ to the Dirac point is $k_D = 4\pi/(3a_0)$ with $a_0 \approx 2.46 \text{ \AA}$ the graphene lattice constant. It is more convenient for us to vary w at fixed $\theta = 1.05^\circ$ as we treat the incommensurate twist via a rational approximant. The magic angle then occurs at $w = 0.11 \text{ eV}$. The DOS of the TBG lattice model is shown in Fig. 2(a), and we focus on the charge neutrality point. Taking the impurity location into consideration, the tunneling strengths in the lattice model mark different sublattice tunneling geometry that is dominated by AA/BB or AB/BA local regions (Fig. 2(b)). The LDOS in each representative region, depicted in Fig. 2(c) away from the magic angle, reflects how the probability density of wavefunctions in the miniband are concentrated near the AA sites, consistent with our ab-initio results and expectations from previous Wannier-function calculations in TBG [66–69].

Finally, the impurity part in the Hamiltonian reads

$$H_{\text{imp}} = \epsilon_d (\hat{n}_{d\uparrow} + \hat{n}_{d\downarrow}) + U \hat{n}_{d\uparrow} \hat{n}_{d\downarrow}. \quad (4)$$

An impurity state with spin σ and on-site repulsion U , localized at the vacancy site R , is created by d_σ^\dagger , has a num-

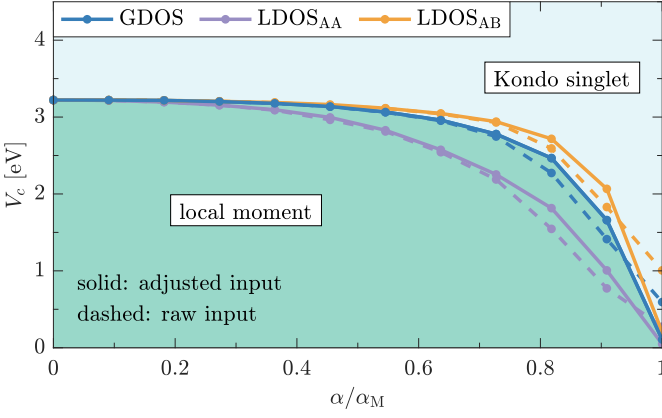

FIG. 3. **Phase diagram for the effective model of TBG with a vacancy** at $T = 0$. The critical hybridization strength V_c that separates the local-moment ($\mu_{\text{eff}} = 1/4$) and Kondo-singlet phase ($\mu_{\text{eff}} = 0$) as a function of $\alpha = w/[2v_F k_D \sin(\theta/2)]$ vanishes linearly at the magic angle $\alpha_M \approx 1/\sqrt{3}$ (cf. Eq. (5)). Dashed lines show results for $\Delta \propto \rho$ with the GDOS ρ or with an LDOS ρ_R (R in the AA or AB region), see Eq. (3). For the solid lines, the input is adjusted to match the analytically known asymptotic low-energy behavior [58].

ber operator $\hat{n}_{d\sigma} = d_{\sigma}^{\dagger} d_{\sigma}$, and an energy ϵ_d measured from the host Fermi energy $E_F = 0$. We choose $U = 2.2$ eV and $\epsilon_d = -0.5$ eV as motivated by our microscopic analysis [58]. Note that the hybridization functions already break particle-hole symmetry and that the TBG half bandwidth (of the full spectrum, not only the miniband) D depends weakly on α , $D(\alpha) \approx 8$ eV. Below, the hybridization strength is either varied or chosen as $V = 1$ eV to estimate the typical T_K . The effective Kondo coupling is $J \sim V^2/U$.

Many-body solution.—To reach sufficiently large system sizes, we have implemented the KPM+NRG method, enabling us to reach a linear lattice size $L = 569a_0$ [65] and a KPM expansion order of $N_C = 2^{18}$ to calculate the Wilson-chain coefficients. We first analyze the $T = 0$ phase diagram for a vacancy in TBG with a variable hybridization strength V and twist parameter α . A single sheet of graphene realizes a clear-cut pseudogap AIM with a local-moment and Kondo-singlet phase. Away from the magic angle, the GDOS of TBG still follows the pseudogap behavior: at low energies, $\rho(\omega) \sim |\omega|/v^2$, where $v = v(\alpha)$ is the renormalized Dirac velocity. As $v(\alpha)$ vanishes at the magic angle (close to $\alpha_M \approx 1/\sqrt{3}$ for the first magic angle in [56]), we may expand it as $v(\alpha) \sim |\alpha - \alpha_M|$ close to α_M . From previous NRG studies, we know that such a particle-hole asymmetric pseudogap AIM has a critical Kondo coupling J_c with $\rho_0 J_c \sim \mathcal{O}(1)$ [35–37, 42, 70]. Hence, from $\rho_0 \sim 1/v^2(\alpha)$, we expect

$$J_c \sim |\alpha - \alpha_M|^2 \quad \Leftrightarrow \quad V_c \sim |\alpha - \alpha_M|. \quad (5)$$

At the magic angle, $\rho(\omega)$ is smooth at low ω with finite $\rho(0)$. Hence, at $T = 0$, a Kondo-singlet phase is found for arbitrarily small V , in agreement with Eq. (5).

Solving the AIM with NRG, we use the impurity contri-

FIG. 4. **Distribution of T_K for different impurity locations across magic-angle TBG.** Here, T_K is given in Kelvin and $V = 1$ eV. We consider roughly 500 (1500) sites for the AA (AB) region. The AB, compared to the AA distribution, is broader, centered at a smaller value, and has a tail reaching down to very low T_K .

bution to the spin susceptibility χ_{imp} to extract the effective magnetic moment $\mu_{\text{eff}} = \lim_{T \rightarrow 0} T \chi_{\text{imp}}(T)$. The local-moment and Kondo-singlet phases are characterized by $\mu_{\text{eff}} = 1/4$ and $\mu_{\text{eff}} = 0$, respectively. Figure 3 shows our numerical results for $V_c(\alpha)$. The results for hybridization functions proportional to an LDOS (for a lattice site in either the AA or AB region) and to the GDOS (equivalent to the LDOS averaged over all lattice sites) behave qualitatively similarly. As expected, in the AA region, the enhanced LDOS leads to a smaller V_c relative to the AB/BA regions. For the GDOS, we know the asymptotic low-energy behavior mentioned before ($\rho(\omega)|_{\alpha \neq \alpha_M} \sim |\omega|$, $\rho(\omega)|_{\alpha_M} = \text{const}$). This allows us to adjust and extend the Wilson-chain input at energy scales below the KPM resolution to match the analytically known behavior [58]. The data with adjusted input nicely reproduces Eq. (5) and confirms our expectations: There is a finite V_c for all $\alpha \neq \alpha_M$, decreasing linearly with α close to α_M , while, at $\alpha = \alpha_M$, any $V > 0$ leads to Kondo screening, consistent with an idealized study using only the GDOS in TBG [71].

Focusing on α_M , where the ground state is always Kondo-screened, we may ask below which T the Kondo-singlet phase occurs across the sample; i.e., we study how T_K changes with the location of the impurity at fixed $V = 1$ eV. We use $T_K \simeq 1/[4\chi_{\text{loc}}]$ [72] as a robust and efficient estimate, where $\chi_{\text{loc}} = \partial_h \langle S^z \rangle|_{h=0}$ (with $\langle S^z \rangle$ the local magnetization) is the local susceptibility computed at $T = 0$. In Fig. 4, we plot the distribution of Kondo scales found for a large number of different sites. There is a strict dichotomy between vacancies in the AA versus AB regions. The LDOS throughout the AA region is rather similar, leading to a narrow distribution of Kondo scales. By contrast, the LDOS in the AB region varies widely at low energies (as it includes V_{AB} and $V_{AB'}$ contributions) and is generally smaller than in the AA region. This leads to a broad distribution of Kondo scales, centered at a smaller value than in the AA region, and with a tail to vanishing T_K . This tail is a measure of the multifractal wavefunc-

tions at the magic angle [73, 74] in TBG, and, when thermodynamic quantities are averaged, this can lead to a non-Fermi liquid response [51, 75].

In reality, the TBG bath we have considered becomes correlated in very close proximity to the magic angle and the non-interacting bath description breaks down. Therefore, at $T=0$, our results are directly applicable across the majority of the phase diagram in Fig. 3, and future work is needed to incorporate the strongly correlated bath that can induce a gap at charge neutrality [76]. At finite temperatures, above the correlated gap, our results serve as a description of the normal state of the defect-induced Kondo effect in TBG.

Conclusion.—Using ab-initio calculations, we embedded a vacancy into pristine TBG and demonstrated how it hybridizes with the low-energy miniband in the vicinity of the magic angle. From this insight, we built an effective AIM that we solved with KPM+NRG [51]. We found a variety of many-body ground states and a pseudogap quantum critical point tunable by the twist angle. At the magic angle, the vacancy is always Kondo-screened, leading to a T_K distribution that is broad in the AB region due to the underlying multifractal single-particle eigenstates [73, 74]. We propose the STM response of such Kondo-induced vacancy states as a probe of the underlying many-body ground states in TBG and potentially moiré materials more broadly.

Acknowledgments.—We thank Kevin Ingersent and Justin Wilson for insightful discussions and collaborations on related work. Y.C. thanks Tawfikur Rakib for help in setting up MD simulations for TBG, and Shang Ren for valuable discussions. I. AB-INITIO STUDY OF MONOVACANCY IN TWISTED BILAYER GRAPHENE

A. DFT simulation of the monovacancy in untwisted bilayer graphene

To study how local atomic environments affect the vacancy resonant states and take into account the V_σ states localized at the nearest neighbor sites, which occur near the Fermi level, we performed density functional theory (DFT) calculation of bilayer graphene with two different registries and three different vacancy configurations: V_{AA} , V_{AB} , $V_{AB'}$. For each bilayer structure, we constructed a 143-atom 6×6 supercell with a single vacancy at the bottom layer. The lattice relaxation and self-consistent-field calculations were performed using the Vienna Ab initio Simulation Package [S1–S3], with a fully spin-polarized Perdew-Burke-Ernzerhof exchange-correlation functional [S4] with a $6 \times 6 \times 1$ k -grid, with a force convergence tolerance $0.05 \text{ eV}/\text{\AA}$. The fully relaxed structures of the three different vacancy configurations exhibit a similar Jahn-Teller distortion near the vacancy, as shown in Fig. S1. The distortions show that one nearest-neighbor carbon atom moves away from the vacancy site, while the other two atoms move closer toward each other to re-bond. The equilibrium bond lengths l_1 , l_1 and l_2 satisfy $l_1 > l_0$ and $l_2 < l_0$, where l_0 is the equilibrium next-nearest-neighbor distance in the pristine single layer graphene.

We also noticed that the relaxation of $V_{AB'}$ takes a particularly long time since the potential energy surface of this type of vacancy is rougher and requires more time to resolve the lowest energy configuration. We plotted the two configurations that are very close in energy for $V_{AB'}$ in Fig. S2. We noticed that one can converge to the correct equilibrium configuration only with a finer k -grid (such as $6 \times 6 \times 1$) and a tighter force convergence tolerance. For the triangle formed by the three nearest-neighbor sites in $V_{AB'}$, there is no carbon site at the top, while for the V_{AA} or V_{AB} , the carbon site at the top of the triangle repels the lone σ and π electrons. Therefore, for $V_{AB'}$, another possible low-energy configuration (Fig. S2 right panel) is when two atoms come further, and one atom moves closer to the vacancy, leaving the total spin moment to be localized around two adjacent sites. While for V_{AA} and V_{AB} , repelled by the center-top carbon, two nearest-neighbor carbon sites always move closer to reform a 2-carbon bound state, significantly lowers the total energy and leads to faster convergence.

We then performed fully spin-polarized self-consistent-field (SCF) calculations on these four structures using a uniform $3 \times 3 \times 1$ Monkhorst-Pack k -grid. The formation energies of these three types of vacancies, computed as $E(N-1) - \frac{N-1}{N}E(N)$ are listed in Table SI, comparable with the $7.0 \pm 0.5 \text{ eV}$ formation energy of a monovacancy in single-layer graphene as experimentally measured [S5]. For all three types of vacancies, the spin density $\rho_\uparrow - \rho_\downarrow$ localizes mainly on the further-away carbon, contributed mostly by the lone σ -electron, and partially by the lone π -electrons. The V_σ state and the zero-mode V_π state are occupied in the spin-up channel and empty in the spin-down

FIG. S1. Relaxed lattice structure of the 6×6 supercell of the bilayer graphene with vacancy systems in three different local environments, named after stacking registry. The vacancy is placed on the bottom layer, denoted by the red cross. The distorted isosceles triangle formed by the three nearest neighbors of the vacancy is denoted by red dots, with the red and blue lines annotating the longer and shorter bonds among them.

FIG. S2. The two $V_{AB'}$ distortions that are close in energies. The spin density $\rho_{\uparrow} - \rho_{\downarrow}$ isosurfaces are plotted for each configuration. We found that one can converge to the correct equilibrium configuration only with a finer k -grid (such as $6 \times 6 \times 1$) and a tighter force convergence tolerance.

	V_{AB}		$V_{AB'}$		V_{AA}	
Formation energy (eV)	5.66		5.64		5.48	
Total spin magnetic moment (μ_B), k : $6 \times 6 \times 1$	1.33		1.43		1.31	
(contribution of V_{σ} and V_{π} (μ_B))	1.0	0.33	1.0	0.43	1.0	0.31
V_{σ} on-site energy ϵ (eV)	-0.45		-0.48		-0.51	
V_{σ} on-site Hubbard U (eV)	2.26		2.21		2.24	
V_{σ} - π bath hybridization strength V (eV)	0.24(3)		0.13(1)		0.12(1)	
(contribution from top layer V (eV))	0.12(1)		0.09(1)		0.07(1)	

TABLE SI. Computed properties of the three vacancy configurations in equilibrium, along with the estimated intra-orbital Hubbard U and on-site energy ϵ for the V_{σ} state and the coarse-grained hybridization V between the V_{σ} and the π bath, in the untwisted bilayer graphene.

channel, both contributing to the $S = 1$ ground state spin density localized around the three nearest-neighbor sites. Because of screening between the V_{π} state and the π bath, the V_{π} state's contribution to the final spin magnetic moment is about $0.4 \mu_B$, resulting in a total spin magnetic moment $\sim 1.4 \mu_B$ (Table SI). In comparison, the spin magnetic moment of the monovacancy in single-layer graphene ranges from 1.04 to $1.84 \mu_B$ [S6]. However, we point out that this discrepancy in μ_{tot} is likely due to a non-converged vertical displacement, sparse k -grid, and small supercell (high defect concentration) [S7]. Our calculation using a $12 \times 12 \times 1$ k -grid yielded 1.23 , 1.36 , and $1.21 \mu_B$ for the three vacancy types listed, slightly smaller than the values given by $6 \times 6 \times 1$ grid listed in Table SI.

In addition, one can estimate the intra-band interaction U for the V_{σ} state. Assuming that the Hubbard model of an isolated impurity applies, the single-particle energies, ~ -0.5 and 1.8 eV, of the V_{σ} (occupied, spin up) and lowest unoccupied spin down V_{σ} states would be ϵ and $\epsilon + U$, i.e., the energies needed for the removing one electron, $|\sigma\rangle \rightarrow |0\rangle$ ($\sigma = \uparrow, \downarrow$) and adding one electron, $|\sigma\rangle \rightarrow |\uparrow\downarrow\rangle$. Here, $|0\rangle$, $|\sigma\rangle$, $|\uparrow\downarrow\rangle$ are the eigenstates of the isolated one-band impurity model, with on-site energy ϵ and Hubbard repulsion U . This allows us to estimate the value of intra-orbital Hubbard interaction U , which is listed in Table SI, in rough agreement with the value of 2.0 eV given by Ref. [S8]. The value is smaller than the intra-orbital onsite Hubbard repulsion computed to be 4.4 eV using the state-of-the-art constrained random phase approximations based on DFT results [S9], and 3.6 eV given by fixed-node diffusion Monte Carlo [S10] for carbon's p_z orbitals.

To study the hybridization of the vacancy states with the itinerant bands, we disentangled the Kohn-Sham wave functions near the Fermi level within a ~ 20 eV window and downfolded to a set of maximally-localized Wannier functions (MLWFs) [S11] using the Wannier90 package [S12–S14]. The initial guess of the projections includes atomic p_z orbitals on each carbon site and three sp^2 orbitals, with their lobes directed towards the vacancy site on the three vacancy nearest-neighbor sites. The converged MLWFs at the three nearest neighbor sites are usually linear superpositions of each site's p_z and sp^2 orbitals. Therefore, we performed a unitary rotation within each 2×2 block such that the two onsite sp^2 and p_z orbitals have zero hopping. Then, we defined the orbital with lower chemical potential as the vacancy sp^2 orbital, and the higher one as the vacancy p_z orbital. Fig. S4 shows the MLWFs after this unitary rotation.

Fig. S5 shows the wave functions of the two localized vacancy states in the spin-up channel, V_{π} and V_{σ} , at Γ . The V_{σ} state is mainly localized at the lone site among the three adjacent sites. In contrast, the V_{π} state (“zero mode”)

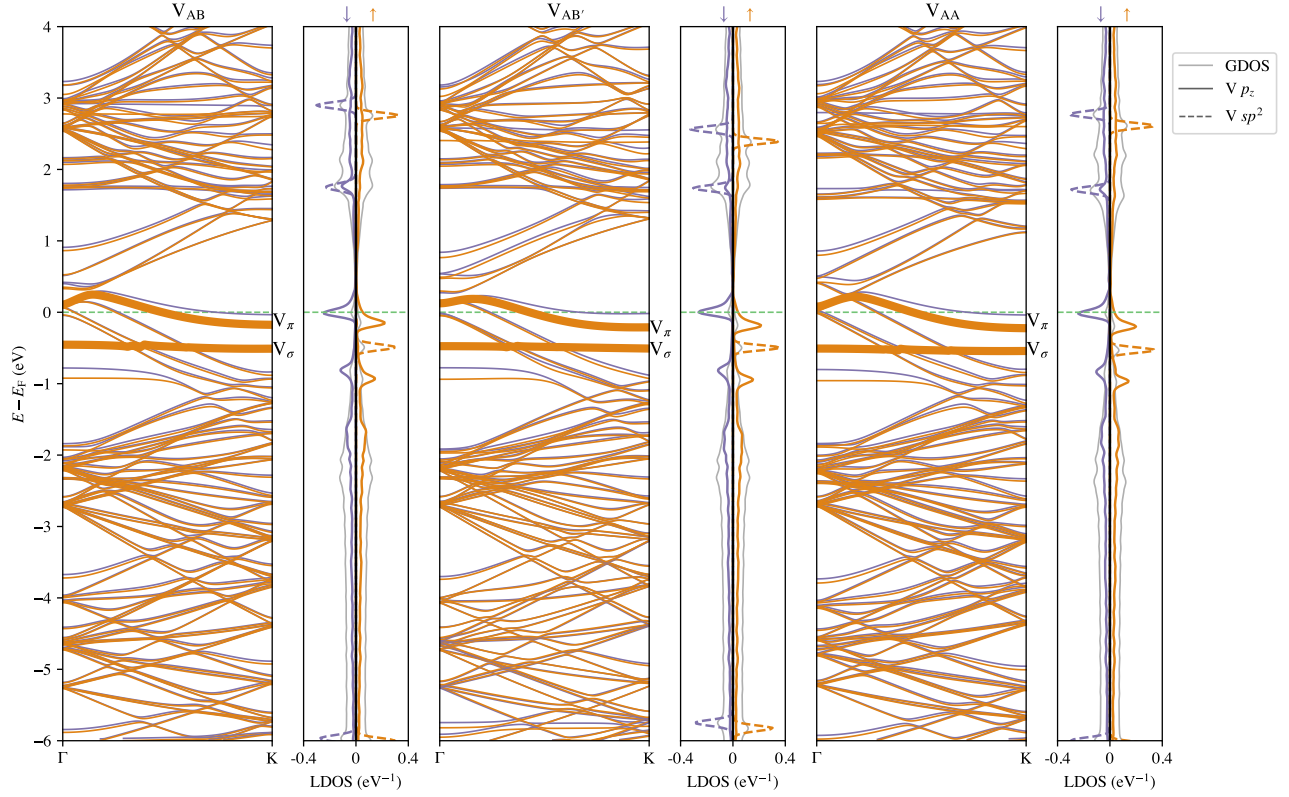

FIG. S3. The bands and local density of states (LDOS) as computed by the tight-binding model derived from Wannierized DFT results for the three vacancy configurations in untwisted bilayer graphene. The two vacancy states of interest, V_π and V_σ , are highlighted by the thick lines on the band structure plot.

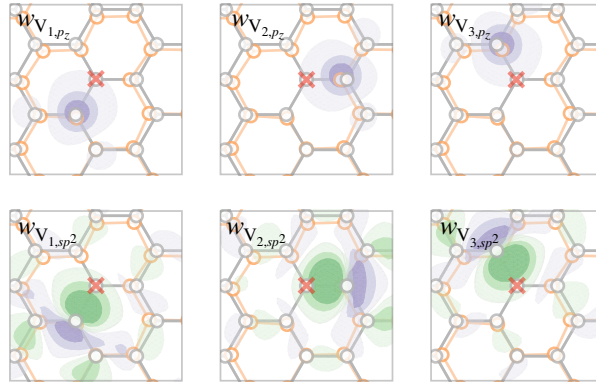

FIG. S4. The rotated maximally localized Wannier functions (MLWFs) at the three adjacent sites of the vacancy in the V_{AA} configuration. The red cross denotes the location of the vacancy site at the bottom layer.

is quasi-localized around the vacancy site, contributed by the dominant sublattice. In the following analysis, we will focus on the hybridization between the V_σ state and the π bath.

B. Local corrugation enhances the V_σ -bath hybridization

We have also studied how local corrugation gives rise to non-zero hybridization between the V_σ states and the π bath in bilayer graphene. Fig. S6(a) shows the atomic positions near the vacancy for the three equilibrium configurations. Compared to the other two cases, $V_{AB'}$ causes more local curvature on the top layer rather than the bottom layer

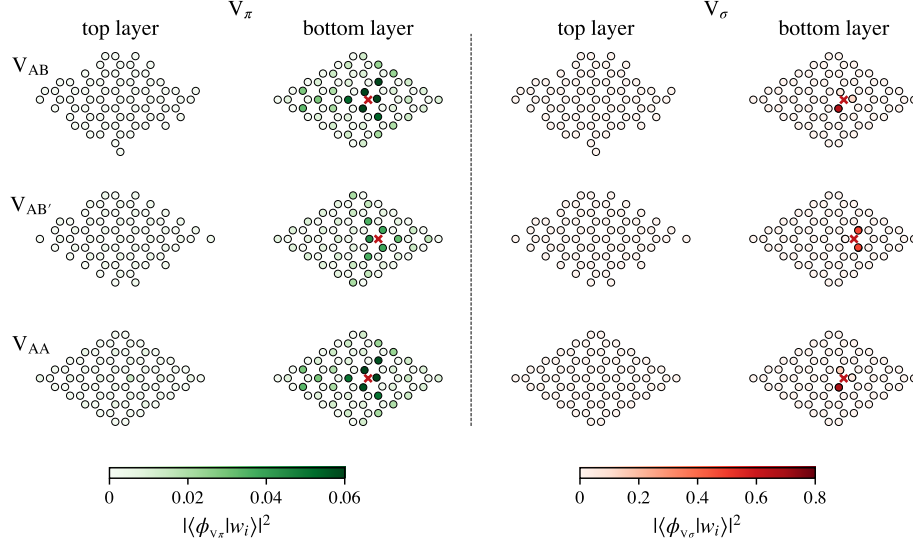

FIG. S5. The probability density projected onto the MLWFs orbitals for the two vacancy states of interest, V_σ and V_π , in V_{AA} configuration. Here, $|w_i\rangle$ is a $(N+2)$ vector, including $(N-1)$ π and 3 σ MLWFs. The dispersion of these two vacancy states is highlighted in Fig. S3. The V_π states are quasi-localized (power-law decay) around the vacancy site, while the V_σ states are exponentially localized at the vacancy adjacent sites.

Twist angle	1.05°			1.35°			2.0°		
	V_{AB}	$V_{AB'}$	V_{AA}	V_{AB}	$V_{AB'}$	V_{AA}	V_{AB}	$V_{AB'}$	V_{AA}
Hybridization strength V (eV)									
in [-200, 200] meV window	0.211(45)	0.135(21)	0.101(12)	0.192(65)	0.069(13)	0.092(12)	0.166(43)	0.075(9)	0.071(12)
in [-20, 20] meV window	0.152(16)	0.094(15)	0.106(2)	0.131(13)	0.062(4)	0.081(4)	0.157(6)	0.075(3)	0.070(2)

TABLE SII. Computed hybridization strength V between the V_σ and the π bath of TBG at various twist angles for the three vacancy configurations at equilibrium, within two chosen energy windows.

where the vacancy resides. Fig. S6(b) shows a distribution of the intra- and inter-layer sp^2 - p_z hoppings versus the distance away from the vacancy sp^2 orbitals. All the absolute values of the hoppings were collected and then averaged over a given bin at some distance. For V_{AA} and $V_{AB'}$ configurations, the nearest intra-layer hoppings are about 0.02 eV, and nearest inter-layer hoppings are halved, about 0.01 eV. For V_{AB} , the intra-layer hoppings are slightly larger, and the nearest inter-layer hoppings are 0.035 eV. This result is consistent with the estimated hybridization strength V for each configuration, as listed in Table SI, i.e., the hybridization between the V_σ and the π bath is mainly contributed by intralayer hoppings, which are caused by the local corrugation near the vacancy in the layer where the vacancy resides. The fact that the equilibrium structure is not completely flat allows the sp^2 and p_z orbitals to hybridize. Particularly, from the last two rows of the table, we see that the V_σ - π bath hybridization strength is further enhanced with the presence of the second layer that breaks the local mirror symmetry of the bilayer, in addition to the small local curvature induced by the vacancy. However, the finite hybridization strength gives a low Kondo temperature, which is not attainable in experiments. Therefore, similar to the situation in the single layer [S15], the local corrugation introduced by the substrate can help greatly increase the Kondo temperature. See Section ID for a detailed study of the effect of local corrugation near the vacancy.

C. Computing the hybridization function between vacancy states and π bath in TBG

In this section, we explain how the hybridization function between the vacancy V_σ state and the π band is computed using the atomic scale model of a pristine TBG [S16], in combination with the Wannierized DFT results of mono-

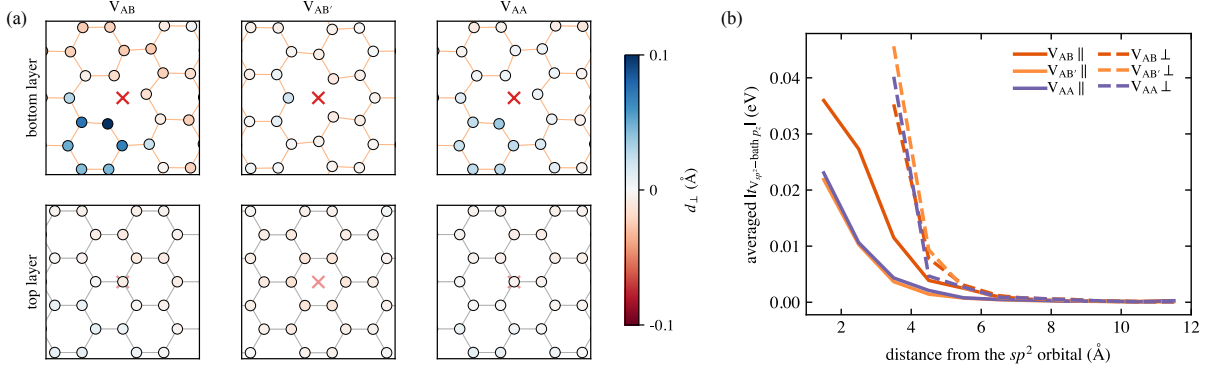

FIG. S6. After the relaxation of the lattice structure, local curvature forms near the regions of the vacancy. This local curvature gives rise to a non-zero intra-layer hopping (t_{\parallel}) between the vacancy sp^2 orbitals and the rest of the p_z orbitals. (a) Position of the atoms from the bottom and top layers of the three configurations, with the atoms colored by their z coordinate away from the averaged position. (b) The absolute values of the intra- (t_{\parallel}) and inter-layer hoppings (t_{\perp}) between the three vacancy sp^2 orbitals and the p_z orbitals, versus the distance away from the vacancy sp^2 orbitals. The values were averaged over the three vacancy-adjacent sites and coarse-grained with respect to the distance. We see that the intra-layer and inter-layer hoppings are of a similar order of magnitudes at equilibrium configurations.

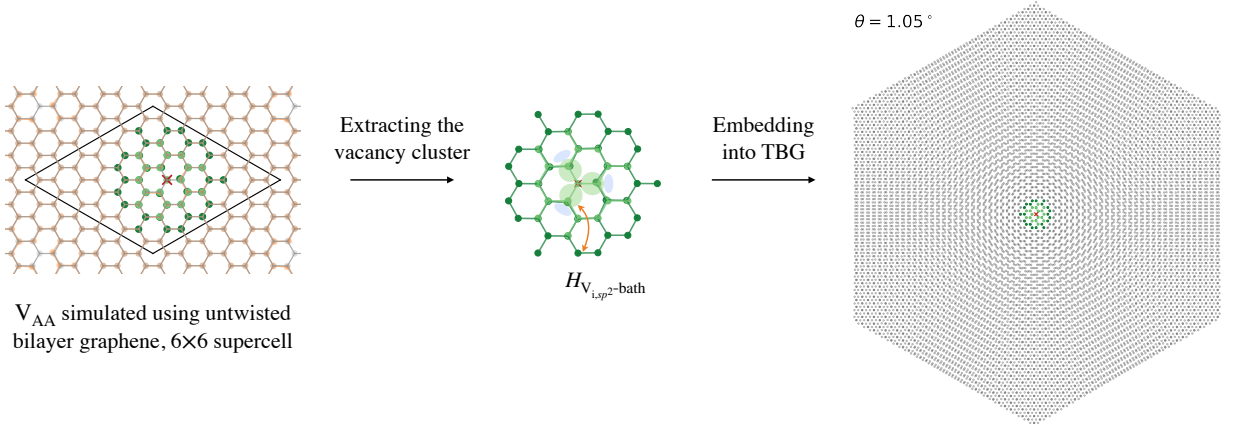

FIG. S7. The schematic of combining the tight-binding Hamiltonian derived from DFT for the monovacancy in untwisted bilayer graphene with the TBG atomic scale model. The dark and light green sites represent the positions of the bath π orbitals from the bottom and top layers, respectively.

vacancy in untwisted bilayer graphene. Fig. S7 shows the workflow of this procedure. We first extract the hopping terms between the vacancy sp^2 orbitals, V_{i,sp^2} ($i = 1, 2, 3$) and the rest of the π orbitals at the $(N - 1)$ bath sites. The wave function $|\phi_{V\sigma}\rangle$ of the vacancy state of interest, V_{σ} , is obtained by diagonalizing the 3×3 block Hamiltonian of the V_{i,sp^2} basis. Then, we diagonalize the atomic-scale tight-binding model H_{TBG} for the pristine TBG as given by Ref. [S16] at twist angle θ and obtain the eigenstates $|\psi_{n\mathbf{k}}\rangle$, written in the π orbital basis. Finally, we find the AB or AA twist centers in TBG, then find the atomic sites in TBG that have the closest local environment with each “bath” site in the untwisted bilayer graphene, chosen to be within 6 Å away from the vacancy site at the bottom layer, and 4 Å away at the top layer. As a result, we constructed the hopping terms between V_{i,sp^2} and the π orbitals in TBG, i.e., $H_{V\sigma\text{-bath}}$. Therefore, by projecting the TBG eigenstates only onto the $(N - 1)$ bath π orbitals, the tunneling elements between $|\phi_{V\sigma}\rangle$ and the n th TBG eigenstates at \mathbf{k} is given by

$$T_{n\mathbf{k}} = \langle \phi_{V\sigma} | H_{V\sigma\text{-bath}} \mathcal{P}_{\text{bath-TBG}} | \psi_{n\mathbf{k}} \rangle. \quad (\text{S1})$$

The hybridization function between the V_{σ} state $|\phi_{V\sigma}\rangle$ and the TBG π bath is given by

$$\Delta_{\text{micro}}(\omega) = \pi \sum_{n,\mathbf{k}} |T_{n\mathbf{k}}|^2 \delta(\omega - E_{n\mathbf{k}}), \quad (\text{S2})$$

FIG. S8. The band structures of the untwisted bilayer graphene with V_{AA} type vacancy with local vertical displacements from 0.05 Å to 0.2 Å (see Fig. 1f for how the three vacancy-adjacent atoms are displaced). The highest occupied (lowest unoccupied) V_σ state is identified for $u_\perp < 0.2$ Å and highlighted in yellow (purple). With $u_\perp = 0.2$ Å, a localized V_σ state is not identifiable due to the strong hybridization with the π bath.

where the subscript “micro” denotes that this hybridization function is obtained from the atomic-scale, microscopic model of the TBG combined with ab-initio downfolded hopping terms obtained from DFT calculations.

We estimated the hybridization strengths V between the V_σ state and the π bath in TBG, within a chosen energy window around the Fermi level, using

$$\Delta_{\text{micro}}(\omega) \approx \pi V^2 \sum_{n,\mathbf{k}} |\langle \psi_{n\mathbf{k}} | w_{\text{vac}} \rangle|^2 \delta(\omega - E_{n\mathbf{k}}), \quad (\text{S3})$$

which is equivalent to equation 3 in the main text. The averaged V is listed in Table IC, where the numbers in the brackets represent the standard deviations of the $V(\omega)$ within the chosen energy window. They are of similar values with the hybridization strengths in untwisted bilayer graphene. Curiously, we noticed that both V_{AB} and $V_{AB'}$ ’s V values show a larger standard deviation, compared with V_{AA} , especially as the twist angle approaches the magic angle 1.05° . We think this is because of the multi-fractal nature of the wave function in magic-angle TBG, which leads to very discontinuous flat-band wave functions in the atomic scale. Therefore, for these two cases, a simple frequency-independent V may not be sufficient to describe the hybridization function $\Delta(\omega)$. (Therefore, further NRG calculations with a more accurate $\Delta(\omega)$ need to be performed, which is beyond the scope of this study.)

Note that we were using the same embedded cluster (see the green atoms Fig. S7) for all these calculations. Therefore, the effect of the local curvature change in the vicinity of the vacancy due to different twist angles was not taken into account. We expect this approximation to apply to small twist angles where, for example, the V_{AA} vacancy only sees its local environment as AA. The AA and AB regions get small in TBG with large twist angles. The local environment of a vacancy located at an AA (or AB) center can not be well approximated by AA- (or AB-) stacked untwisted bilayer graphene.

D. Local corrugation away from equilibrium

In a free-standing (no substrate) magic-angle TBG, the two layers naturally corrugate to lower its total energy, such that the interlayer distance in the AA regions is larger, and that in the AB regions is smaller. This natural corrugation is shown in Fig. 2(c) in the main text, where the positions of the C atoms in the TBG at $\theta = 1.05^\circ$ given by MD calculations are plotted, color-coded by their interlayer distances. However, we do not expect this natural corrugation introduced by twisting to enhance the hybridization significantly. This vertical corrugation is $\lesssim 0.1$ Å [S17] in the moiré scale, and is therefore < 0.01 Å near the vacancy. In order to achieve an experimentally detectable Kondo temperature (> 1 K) for the vacancies in the AA regions, one needs to introduce local corrugations, especially near the vacancy, which greatly enhances the hybridization strength between the vacancy state V_σ and the bath. This could be achieved via coupling to a substrate that interacts slightly stronger with TBG compared with the widely used hBN [S15].

To systematically study the effect of local corrugation in enhancing the V_σ -bath hybridization V in untwisted bilayer graphene, and how this property gets preserved in TBG, we manually introduced vertical displacement for the

FIG. S9. (a-c) The computed hybridization strength for the three vacancy types, with ad-hoc local corrugations. (d) V versus the twist angle at $u_{\perp} = 0.1 \text{ \AA}$. The hybridization strength of V_{AA} vacancy is more sensitive to the twist compared to the other two AB-type vacancies. (e) The hybridization function for the $V_{AB'}$ in equilibrium configuration (upper panel) and the LDOS at the corresponding vacancy site, and the LDOS sum for the vacancy site and the three adjacent sites. We can see that the vacancy site of $V_{AB'}$ has almost zero contributions to the flat band DOS; when computing the value V , it would have a large uncertainty if one were to divide $\Delta(\omega)$ by the LDOS at only the vacancy site. Instead, we use the averaged LDOS of the vacancy and the three adjacent sites.

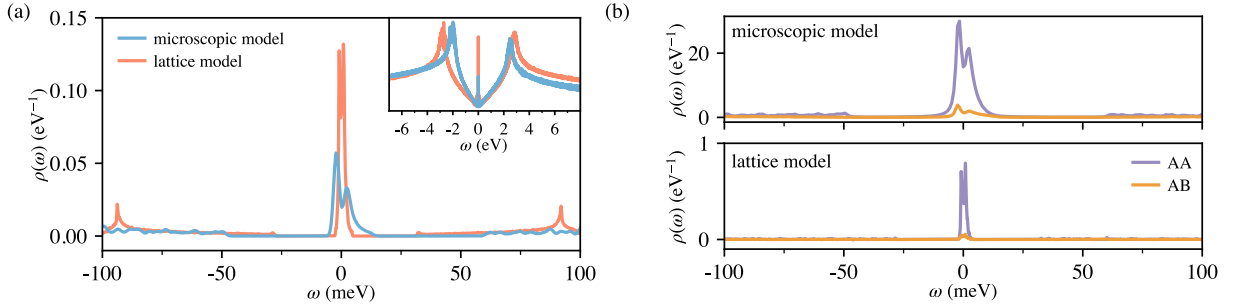

FIG. S10. A comparison of the GDOS and LDOS in AA and AB sites given by the two models: $\theta = 1.05^\circ$ microscopic model and $w = 0.11 \text{ eV}$ lattice model. Both these two models agree on the overall features of the GDOS (panel (a)) and LDOS (panel (b)). In NRG calculations, we chose to use the GDOS and LDOS produced by the lattice model to construct the hybridization function, which allows us to reach a larger system size and achieve higher resolution near the Fermi level.

three adjacent atoms near the vacancy and performed similar calculations as shown in section IC. We chose multiple vertical displacements u_{\perp} , then extracted V for the untwisted bilayer graphene, and TBG with chosen twist angles. Specifically, we moved the isolated, unbonded C atom upper by u_{\perp} and the other two bonded atoms lower by u_{\perp} . This fashion of introducing local corrugation is ad hoc, which is merely an attempt to mimic the substrate-induced local corrugation that was observed in experiments [S15] and to maximize the hybridization between the V_{σ} states and the π bath. To justify this, we performed two calculations: A. only displacing the isolated C atom by $+u_{\perp}$, and B. displacing the isolated C atom by $+u_{\perp}$ and the other two atoms by $-u_{\perp}$. For the V_{AA} vacancy with $u_{\perp} = 0.5 \text{ \AA}$, configuration A gives a hybridization strength $1.25(2) \text{ eV}$, smaller by $\sim 24\%$ than that given by configuration B. Therefore, we chose to displace the atoms using configuration B in order to maximize the hybridization strength.

The V values for V_{AA} were presented in Fig. 1(g). Here, we show the band structure plots for the chosen corrugations in Fig. S8. We see directly from the energies of the V_{σ} states in the spin up and down channels that the value of Hubbard U slightly decreases by $\sim 0.1 \text{ eV}$ as u_{\perp} increases to 0.1 \AA (note the position of the lowest unoccupied spin-down V_{σ} state as highlighted in the light purple box), and the onsite energy ϵ almost does not change. However, the value of the total magnetic moment μ_{tot} decreases from $1.31 \mu_B$ to $1.17 \mu_B$ at $u_{\perp} = 0.1 \text{ \AA}$. In Fig. S9, we summarized the hybridization strengths for the three vacancy types as a function of the vertical displacement and the twist angle. Specifically, for $V_{AB'}$, the value of V is computed as $V = \sqrt{\Delta(\omega)/\bar{\rho}(\omega)}$, where $\bar{\rho}(\omega) = \frac{1}{4} \sum_{i \in \{\text{vac}, 3 \text{ adj-sites}\}} \rho_i(\omega)$, instead of just the LDOS at the vacancy site, which otherwise gives a huge uncertainty in V since the LDOS at the vacancy site almost vanishes near E_F (see Fig. S9(e)).

E. Comparison between the microscopic model and the lattice model

For NRG calculations, we used the parameters computed from our microscopic modeling of the TBG+vacancy system and the local density of states given by the lattice model (described in section II) to construct the hybridization

function. The lattice model allows for finer resolution of the hybridization function near the Fermi level since a larger system size is more attainable. Fig. S10 shows a direct comparison between the GDOS and the LDOS of the two models ($\theta = 1.05^\circ$ microscopic model and $w = 0.11$ eV lattice model). Both these two models agree on the overall features of the GDOS, i.e., they reproduce the flat band of a small bandwidth (20 meV for the microscopic model, 8 meV for the lattice model). As for the LDOS, both models reproduce the correct features in the AA and AB sites that the flat bands are more localized at the AA sites than the AB sites.

II. LATTICE MODEL OF TBG

The impurity host is a microscopic lattice model of TBG around the charge neutrality point where the angle enters as a free parameter [S18], which is derived from the Bistritzer–MacDonald continuum model [S19], and it has three main components

$$H_{\text{host}} = H_0 + H_{T_0} + H_{T_1}. \quad (\text{S4})$$

Here, H_0 denotes the lattice model of two independent Dirac cones, representing the two independent layers of graphene

$$H_0 = \sum_{\mathbf{r}, l} t \left[c_{\mathbf{r}, l}^\dagger \sigma_x c_{\mathbf{r}, l} + \sum_{j=1}^2 (c_{\mathbf{r}+\mathbf{a}_j, j}^\dagger \sigma^+ c_{\mathbf{r}, l} + \text{H.c.}) \right], \quad (\text{S5})$$

where $t = 2.8$ eV, \mathbf{r} labels points on the triangular lattice, $c_{\mathbf{r}, l} = (c_{\mathbf{r}, A, l}, c_{\mathbf{r}, B, l})^T$ a pseudospinor operator, and layer $l = 1, 2$ with sublattices A, B. The tunneling between layers in real space is separated into two parts

$$\begin{aligned} H_{T_0} &= \sum_{\mathbf{r}} [c_{\mathbf{r}, 2}^\dagger \mathcal{T}_0(\mathbf{r}) c_{\mathbf{r}, 1} + \text{H.c.}], \\ H_{T_1} &= \sum_{\mathbf{r}} \sum_{n=1}^6 \left[(-1)^n c_{\mathbf{r}+\mathbf{a}_n, 2}^\dagger \mathcal{T}_1 \left(\mathbf{r} + \frac{\mathbf{a}_n}{2} \right) c_{\mathbf{r}, 1} + \text{H.c.} \right], \end{aligned} \quad (\text{S6})$$

where H_{T_0} denotes the interlayer tunneling at site \mathbf{r} , while H_{T_1} represents tunneling to the nearest neighbors on the triangular lattice of the other layer ($\mathbf{a}_n, n = 1, 2, \dots, 6$ are nearest-neighbor lattice vectors, $\mathbf{a}_1 = (\sqrt{3}/2, 3/2)d$, $\mathbf{a}_2 = (-\sqrt{3}/2, 3/2)d$, $\mathbf{a}_3 = (-\sqrt{3}, 0)d$, and $\mathbf{a}_j = -\mathbf{a}_{j-3}$ for $j = 4, 5, 6$. d is the nearest C atom distance. The lattice constant is $a_0 = |\mathbf{a}_j| = \sqrt{3}d$. The tunneling matrices are given by

$$\begin{aligned} \mathcal{T}_0(\mathbf{r}) &= \sum_{j=1}^3 \begin{pmatrix} w_0 \cos(\xi_{j,-}) & w_1 \cos(\zeta_{j,-}) \\ w_1 \cos(\zeta_{j,+}) & w_0 \cos(\xi_{j,+}) \end{pmatrix}, \\ \mathcal{T}_1(\mathbf{r}) &= \frac{1}{3\sqrt{3}} \sum_{j=1}^3 \begin{pmatrix} w_0 \sin(\xi_{j,-}) & w_1 \sin(\zeta_{j,-}) \\ w_1 \sin(\zeta_{j,+}) & w_0 \sin(\xi_{j,+}) \end{pmatrix}, \end{aligned} \quad (\text{S7})$$

where w_0, w_1 denotes the AA and AB tunneling, respectively. In the following, we define $w = w_1$ and fix the relation $w_0 = 0.75w$. The abbreviations are

$$\begin{aligned} \xi_{j,\pm} &= \mathbf{q}_j \cdot \mathbf{r} + \phi_j \pm \frac{1}{2}\theta, \\ \zeta_{j,\pm} &= \mathbf{q}_j \cdot \mathbf{r} \pm \frac{2}{3}\pi(j-1) + \phi_j, \end{aligned} \quad (\text{S8})$$

where θ is the twist angle contained in the twist wavevector $k_\theta = 2k_D \sin(\theta/2)$ with $k_D = 4\pi/(3\sqrt{3}d) = 4\pi/(3a_0)$. The three vectors are controlled by the k_θ as $q_1 = k_\theta(0, -1)$, $q_2 = k_\theta(\sqrt{3}/2, 1/2)$ and $q_3 = k_\theta(-\sqrt{3}/2, 1/2)$. ϕ_j are three global random phases. To ensure the boundary tunneling strengths are consistent, we need extra constraints in the system sizes L of the lattice, i.e., $\text{mod}(q_j(\theta)L_x|y, 2\pi) \approx 0$ for each θ . At the fixed angle $\theta = 1.05^\circ$, we choose $L \equiv L_x = L_y = 569a_0$. The boundary condition is taken to be a twisted boundary condition, i.e., a random twisted phase ψ on the hopping matrix elements at the (right) boundaries $t \rightarrow te^{i\psi}$.

Note that the particle-hole symmetry cannot be preserved in lattice models of TBG [S20] from the topology point of view. For each value of w , we shift the chemical potential (upon averaging twisted boundary conditions) to ensure charge neutrality.

III. KERNEL POLYNOMIAL METHOD

We computed the density of states using the kernel polynomial method (KPM). It is an approximation that expands a function using Chebyshev polynomials,

$$f(x) = \frac{1}{\pi\sqrt{1-x^2}} \left[g_0\mu_0 + 2 \sum_{n=1}^{\infty} g_n\mu_n T_n(x) \right], \quad (\text{S9})$$

where $T_n(x)$ s are the Chebyshev functions and $T_n(x) = \cos(n \arccos(x))$, $\mu_n = \int_{-1}^1 f(x) T_n(x)$ are the KPM expansion moments with Jackson kernel g_n [S21]. For the case of the global density of states (GDOS), the variable is E and we have,

$$\mu_n = \int_{-1}^1 \rho(E) T_n(E) = \frac{1}{D} \sum_{k=0}^{D-1} \langle k | T_n(H) | k \rangle = \frac{1}{D} \text{Tr}(T_n(H)), \quad (\text{S10})$$

where E is normalized to $[-1, 1]$, and the trace is evaluated stochastically with the number of random vectors N_R for the D states. The local density of states (LDOS) at site i is given by

$$\mu_n = \frac{1}{D} \langle i | T_n(H) | i \rangle. \quad (\text{S11})$$

To compute the density of states (DOS) with lattice size 569×569 , we used 2 random vectors ($N_R = 2$), and a number of expansions $N_C = 2^{18}$. The results were then averaged over a set of twisted boundary conditions, each of which was generated as a two-dimensional random phase vector and multiplied to the boundary Hamiltonian matrix entree.

The Wilson parameters for the NRG with certain logarithmic discretization Λ can be obtained from the GDOS/LDOS once the moments μ_n is computed [S22]. The key quantities are the integration of zeroth and the first moment of energies over logarithmic bins

$$\alpha_m^{\pm} = \pm \int_{\pm\tilde{\epsilon}_{m+1}}^{\pm\tilde{\epsilon}_m} \tilde{\Delta}(\tilde{\epsilon}) d\tilde{\epsilon}, \quad \beta_m^{\pm} = \pm \int_{\pm\tilde{\epsilon}_{m+1}}^{\pm\tilde{\epsilon}_m} \tilde{\epsilon} \tilde{\Delta}(\tilde{\epsilon}) d\tilde{\epsilon}, \quad (\text{S12})$$

where the tilde denotes the normalized energy and hybridization (GDOS/LDOS) and the logarithmic discretization $\tilde{\epsilon}_{m+1} < \pm\tilde{\epsilon} < \tilde{\epsilon}_m$, where

$$\tilde{\epsilon}_0 = 1, \quad \tilde{\epsilon}_m = \Lambda^{1-z-m} \quad \text{for } m = 1, 2, \dots \quad (\text{S13})$$

Using $T_n(x) = \cos(n \arccos x)$, and defining $\theta_m = \arccos \tilde{\epsilon}_m$ with $0 \leq \theta_m \leq \pi/2$ for $m = 0, 1, 2, \dots$, one can show that

$$\alpha_m^{\pm} = \frac{1}{\pi} \left[g_0\mu_0(\theta_{m+1} - \theta_m) + 2 \sum_{n=1}^{N_C-1} \frac{(\pm 1)^n}{n} g_n\mu_n (\sin n\theta_{m+1} - \sin n\theta_m) \right], \quad (\text{S14})$$

and

$$\begin{aligned} \beta_m^{\pm} = \frac{1}{\pi} & \left[g_1\mu_1(\theta_{m+1} - \theta_m) + \sum_{n=1}^{N_C-2} \frac{(\pm 1)^n}{n} (g_{n-1}\mu_{n-1} + g_{n+1}\mu_{n+1}) (\sin n\theta_{m+1} - \sin n\theta_m) \right. \\ & \left. + \sum_{n=N_C-1}^{N_C} \frac{(\pm 1)^n}{n} g_{n-1}\mu_{n-1} (\sin n\theta_{m+1} - \sin n\theta_m) \right]. \end{aligned} \quad (\text{S15})$$

Equations (S14) and (S15) are then inserted into the standard NRG unitary transformation to yield the Wilson-chain coefficients ε_n and t_n [S23].

IV. NUMERICAL RENORMALIZATION GROUP

We used an NRG discretization parameter of $\Lambda = 3$ and kept up to 2000 SU(2) multiplets during the iterative diagonalization. The impurity contribution to the spin susceptibility was computed as a thermodynamic property

FIG. S11. Distribution of T_K for different impurity locations across magic-angle TBG, analogously to Fig. 4 in the main text, but at smaller hybridization strengths $V=0.75$ eV and $V=0.5$ eV.

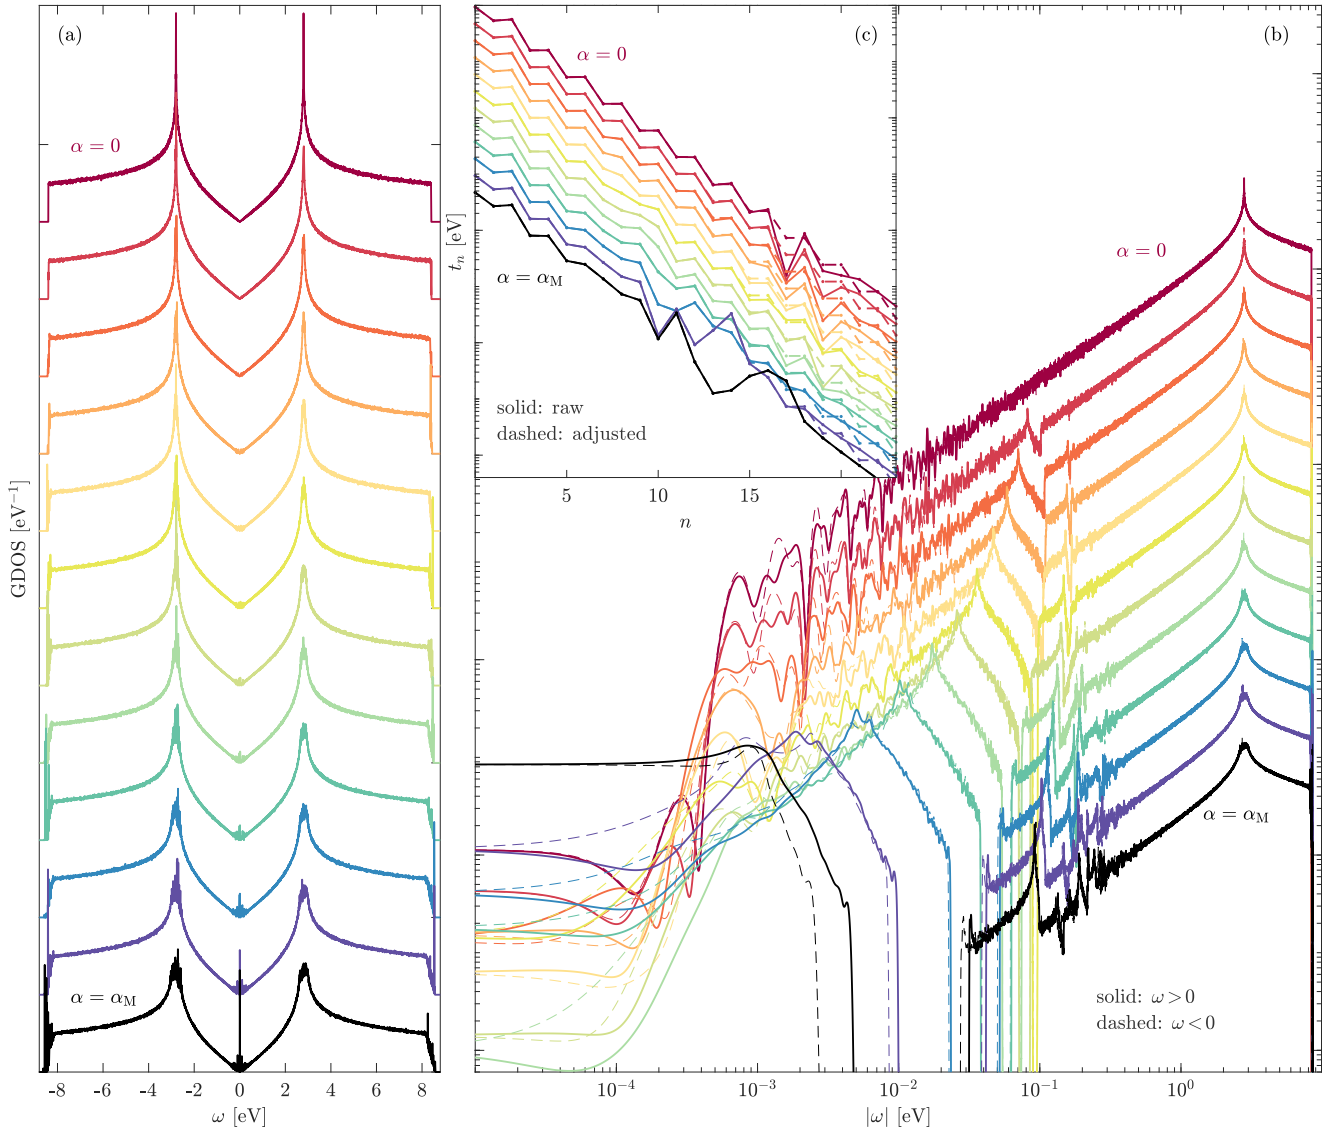

FIG. S12. GDOS for various twist angles on (a) linear and (b) logarithmic scales. (c) Corresponding hopping amplitudes along the Wilson chain. All lines are shifted vertically for visualization.

(we average over several values of $\bar{\beta}$ on the order of 1, cf. Eq. (45) in Ref. [S23]). The local spin susceptibility was computed within the full density-matrix NRG [S24, S25]. To demonstrate how sensitive T_K is to V , we plot in Fig. S11 the distribution of Kondo temperatures, analogously to Fig. 4 in the main text, but at two lower values of V .

Figure S12 shows the GDOS for various twist angles from $\alpha=0$ to α_M on linear and logarithmic scales, together with the corresponding hopping amplitudes along the Wilson chain t_n . All lines are shifted vertically for visualization. Consider $\alpha < \alpha_M$ first. From the log-log plot of the GDOS, one sees that all curves behave as $\rho(\omega) \propto |\omega|$ for low frequencies, but the KPM resolution is low below $|\omega| \lesssim 10^{-2}$ eV and breaks down for $|\omega| \lesssim 10^{-3}$ eV. Accordingly, the Wilson chain hopping parameters t_n become irregular for $n \gtrsim 15$ and spuriously flat for $n \gtrsim 20$ (as the GDOS levels off below the resolution limit). For α closer α_M , more low-energy states are available to KPM and the low-energy resolution becomes better. At α_M , ρ is actually flat at low energy and the t_n actually follow the asymptotic $\Lambda^{-n/2}$ behavior, so the resolution limit is not seen. To overcome the KPM resolution limit for $\alpha < \alpha_M$ and access arbitrarily small energy scales (for all α), we adjust and extend the Wilson chain parameters using the analytically known asymptotic behavior as in Eqs. (28) and (29) of Ref. [S26] for $\alpha < \alpha_M$ and Eq. (32) of Ref. [S23] for $\alpha = \alpha_M$.
